Outpatient Management of Severe COPD

Dennis E. Niewoehner, M.D.

This Journal feature begins with a case vignette highlighting a common clinical problem. Evidence supporting various strategies is then presented, followed by a review of formal guidelines, when they exist. The article ends with the author’s clinical recommendations.

A 67-year-old man presents with a history of dyspnea, which has progressed for the past several years. He began smoking cigarettes at 15 years of age and continues to smoke one pack per day. Worsening breathlessness forced him to retire as a laborer, and he has sought emergency care for what he calls bronchitis twice in the past year. His physical examination is notable for diminished breath sounds on auscultation, with a prolonged expiratory phase. Spirometry reveals severe airflow obstruction (ratio of forced expiratory volume in 1 second [FEV₁] to forced vital capacity [FVC], 0.43; FEV₁, 34% of the predicted value). How should this case be managed?

The Clinical Problem

The sentinel clinical feature of severe chronic obstructive pulmonary disease (COPD) is dyspnea on exertion. Its onset is usually insidious, and it may progress to severe disability over a period of years or decades. Other common symptoms include cough, sputum production, wheezing, and chest congestion. The principal pathophysiological features of COPD are shown in Figure 1. Patients with severe COPD often have exacerbations that result in medical visits and hospitalizations. Chronic hypoxemia and hypercapnia may cause pulmonary hypertension and cor pulmonale. Patients with severe COPD are also at increased risk for other systemic diseases, including cardiovascular disease, osteoporosis, lung cancer, and depression.¹

COPD represents a growing global public health problem. In one population-based study conducted at multiple international sites, approximately 10% of participants 40 years of age or older were found to have airflow obstruction of at least moderate severity according to spirometric criteria.² Between 1970 and 2002, age-standardized rates of death from COPD increased by 103% in the United States, making it the fourth leading cause of death.³ Women accounted for most of this increase, and the rate of death from COPD among women now exceeds the rate among men.⁴ As COPD worsens, there is a precipitous increase in health care costs, much of which is attributable to hospital care for exacerbations.⁵

Strategies and Evidence

History and Physical Examination

Although COPD is more common with increasing age, it should be considered in all adults who report chronic respiratory symptoms, particularly dyspnea that limits ordinary activities. Cigarette smoking is by far the most important known cause of COPD, but clinically significant disease develops in only a small proportion of smokers. Other environmental risk factors, such as exposure to various industrial dusts and fumes, have also been identified.⁶,⁷ Physical examination may reveal a
barrel-shaped chest, inspiratory retraction of the lower ribs (Hoover’s sign), a prolonged expiratory phase, and use of the accessory muscles of respiration, but these findings are sometimes absent even in cases of severe disease.

SPIROMETRY AND OTHER TESTING

A medical history and physical examination may suggest COPD, but they are not reliable predictors of airflow obstruction; the diagnosis must be confirmed with the use of spirometry. A Frequent-
ly, however, spirometry is not performed, and failure to obtain spirometric confirmation leads to misdiagnosis in many cases. Airflow obstruction as measured by spirometry is defined as a ratio of the postbronchodilator FEV₁ to FVC of less than 0.70. When airflow obstruction is present, its severity is classified according to the FEV₁ as a percentage of the predicted normal value (Table 1). Spirometry is essential in determining whether the probable cause of respiratory symptoms is COPD, but clinical criteria, such as the intensity of breathlessness in relation to specific tasks and the frequency of exacerbations, should also be used when evaluating the overall severity of disease. Testing the reversibility of airflow obstruction with an inhaled bronchodilator may be of value at the initial evaluation because a very strong response might identify previously unsuspected asthma. An early age at the onset of symptoms, atopy, the absence of a history of smoking, episodic symptoms, and nighttime awakening are more suggestive of asthma than of COPD.

Labeling patients with COPD as “responders” or “nonresponders” according to arbitrary reversibility criteria is of little practical value because the improvement in lung function with bronchodilators, whether immediate or eventual, is small relative to measurement error. Consequently, spirometry is a poor guide for determining whether therapy should be continued or modified in an individual patient. Once a diagnosis of COPD has been established, there is usually little reason to repeat spirometry at subsequent visits, although serial spirometric measurement at yearly intervals (or longer) may provide some prognostic information. On occasion, it may be helpful in distinguishing pulmonary from nonpulmonary causes of worsening dyspnea.

A chest radiograph should be obtained to rule out other pulmonary diseases. Chest imaging with computed tomography is unnecessary unless another diagnosis is suspected or surgical therapy for COPD is being considered. Oximetry should be performed annually, particularly in patients with severe or very severe disease, since patients with chronic hypoxemia benefit from long-term oxygen therapy. Testing for genetically determined deficiencies of alpha₁-antitrypsin may be considered, particularly if COPD develops at a relatively young age or if there is a strong family history. This information may be useful for counseling purposes. Alpha₁-antitrypsin replacement therapy is available, though of uncertain benefit.

### SMOKING CESSATION

In the Lung Health Study, a randomized trial of smoking cessation in patients with mild-to-moderate COPD, cessation of smoking slowed the decline in lung function and, at long-term follow-up, reduced the rate of death from any cause. Although similar studies involving patients with severe COPD have not been conducted, it is reasonable to assume that some health benefits accrue from smoking cessation at all stages of the disease. Information about smoking-cessation interventions targeted to patients with COPD is limited, so combinations of counseling and pharmacotherapy that are effective in the general population should also be used with these patients.

### BRONCHODILATORS

Many patients with severe COPD obtain symptomatic relief from the use of inhaled bronchodilators. Short-acting β₂-adrenergic agonists (e.g., albuterol) and ipratropium bromide, a short-acting anticholinergic agent, are used singly and in combination. Long-acting bronchodilators are now commonly used, but a short-acting bronchodilator should be provided for rescue therapy (Table 2). Many patients prefer albuterol to ipratropium bromide because it is faster acting.

The inhaled long-acting β₂-agonists salmeterol and formoterol provide sustained bronchodilation for at least 12 hours, and the inhaled long-acting anticholinergic agent tiotropium for

| Combination β\textsubscript{2}-adrenergic agonist bronchodilator–inhaled corticosteroid |                                                |                               |
| Fluticasone–salmeterol (dry powder)† | inhaler: 250 µg fluticasone, 50 µg salmeterol per inhalation; 1 inhalation twice daily | Sore throat, dysphonia, headache, nasopharyngitis, thrush, hypersensitivity reaction, possible pneumonia, dizziness, tremor, throat irritation |
| Budesonide–formoterol† | inhaler: 160 µg budesonide, 4.5 µg formoterol; 2 inhalations twice daily‡ |                               |
| Methylxanthine: theophylline (24-hr sustained-release formulation) | pill: 200 to 800 mg per day, with low starting dose increased to obtain serum concentration of 8 to 12 µg/ml; once daily | Nausea and vomiting, seizures, tremor, insomnia, multifocal atrial tachycardia, hypersensitivity reaction |

\textsuperscript{*} This is not a complete list of medications used for chronic obstructive pulmonary disease (COPD). 
\textsuperscript{†} This is the only formulation of this specific combination of drugs approved by the Food and Drug Administration for treatment of COPD. 
\textsuperscript{‡} The dose of budesonide in the metering chamber is 180 µg, but the dose delivered to the patient is 160 µg.
tion, and this may be their most important clinical benefit.\textsuperscript{14,21,22} Given that the average patient with severe COPD has about one exacerbation per year that requires medical attention, five to seven patients must be treated for 1 year to prevent a single event. Both classes of drugs have been shown to reduce hospitalizations, although the reductions have not been consistent.\textsuperscript{21,22}

Adverse events associated with long-acting bronchodilators are generally minor (Table 2). Although concerns have been raised about the cardiovascular safety of both classes of long-acting bronchodilators,\textsuperscript{23,24} no serious safety problems were identified in two large trials, one comparing salmeterol with placebo in 3045 patients followed for 3 years,\textsuperscript{24} and another comparing tiotropium with placebo in 5993 patients followed for 4 years.\textsuperscript{22}

Theophylline is infrequently used in current practice but may be considered in patients whose COPD is difficult to control. The target plasma level should be no higher than 12 \( \mu \)g per milliliter; higher levels are poorly tolerated in older patients.

**INHALED CORTICOSTEROIDS**

Inhaled corticosteroids are also widely prescribed for COPD. Similar to long-acting bronchodilators, inhaled corticosteroids reduce the frequency of exacerbations by 15 to 20\% and also improve respiratory health status, but only modestly.\textsuperscript{14,21,22} The combination of an inhaled corticosteroid with a long-acting \( \beta_2 \)-agonist reduces exacerbations by about an additional 10\% as compared with either therapy used alone.\textsuperscript{21}

Dysphonia and upper-airway thrush are the most common adverse events associated with inhaled corticosteroids. They have also been linked to an increased risk of pneumonia in patients with COPD, amounting to about 3 excess cases per 100 patient-years of exposure.\textsuperscript{25} However, the significance of this observation is uncertain, since chest radiographs were not required for the diagnosis of pneumonia, and inhaled corticosteroid use was not associated with increased mortality.

**OXYGEN**

Two randomized trials evaluated the use of oxygen therapy in patients with severe COPD and persistent hypoxemia.\textsuperscript{26,27} One was a 5-year study that compared the effects of oxygen use for 15 hours per day with no oxygen use. The other was a 3-year study of oxygen use for 18 hours per day as compared with 12 hours per day. Oxygen therapy proved beneficial: there was an absolute reduction in the rate of death from any cause of about 20 percentage points in both trials.

Arterial oxygen levels should be assessed when the patient is clinically stable, at rest, and breathing ambient air. If the partial pressure of arterial oxygen is at or below 55 mm Hg, or if the arterial oxygen saturation is at or below 88\%, home use of oxygen should be prescribed for at least 18 hours daily, including sleep time, with flow rates that maintain the oxygen saturation above 90\%. In randomized trials, home use of oxygen conferred no apparent survival advantage among patients with milder resting daytime hypoxemia (partial pressure of arterial oxygen, 56 to 65 mm Hg) or isolated nocturnal hypoxemia.\textsuperscript{28,29}

Clinicians frequently prescribe ambulatory oxygen therapy for patients who have normal oxygen levels at rest but who have transient desaturation during exercise. Some patients report that ambulatory oxygen therapy helps relieve exercise-related breathlessness. Whether this perceived benefit is due to oxygen supplementation or to a placebo effect remains unclear. Short-term, placebo-controlled trials have shown that oxygen therapy improves exercise endurance in a laboratory setting; however, efforts to show that ambulatory oxygen use improves respiratory quality of life or relieves symptoms during activities of daily living have been mostly unsuccessful.\textsuperscript{30,31}

**MANAGEMENT OF EXACERBATIONS**

Severe exacerbations of COPD have an adverse effect on health status and may cause permanent loss of lung function.\textsuperscript{32,33} Most exacerbations are thought to result from infection, but sputum smears and cultures offer little help in guiding therapy.

As compared with placebo, antibiotics decrease the relative risk of treatment failure (defined as no resolution or clinical deterioration) by approximately 50\% when used for COPD exacerbations.\textsuperscript{34} Subgroup analysis suggests that antibiotics are most effective when cough and sputum purulence are present. Most trials suggesting the efficacy of antibiotics have compared the use of older antibiotics, such as amoxicillin,
trimethoprim–sulfamethoxazole, and the tetracyclines, with placebo. It is uncertain whether newer classes of antibiotics, such as macrolides and fluoroquinolones, are more effective. Initial outpatient treatment with antibiotics should be based on considerations of cost, safety, and local patterns of antibiotic resistance among the bacterial species commonly isolated from sputum during exacerbations, particularly *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. In randomized trials, the use of systemic corticosteroids as compared with placebo reduced the relative risk of treatment failure (as defined by intensification of therapy, rehospitalization, or a return to the emergency department) by about 30% in patients with COPD exacerbations who were hospitalized or seen in an emergency department. Severely symptomatic patients seen in an outpatient setting are also likely to benefit from systemic corticosteroids, although data from trials of outpatient corticosteroid therapy for severe symptoms are lacking. In most instances, 40 mg of prednisone taken once daily for 10 to 14 days should suffice. Courses of treatment that are extended for more than 14 days confer no added benefit and increase the risk of adverse events.

If an exacerbation is associated with increased breathlessness, patients should be encouraged to increase their use of short-acting bronchodilators. Anticholinergic and β₂-agonist bronchodilators appear to be equally effective, with little additive benefit from combined use.

### Immunizations

Recommendations for influenza and pneumococcal vaccinations for patients with COPD are summarized in Table 3.

### Pulmonary Rehabilitation

As airflow obstruction progresses, patients with COPD typically become increasingly sedentary, which leads to muscular and cardiovascular deconditioning. Increasing physical disability contributes to social isolation and depression, which are highly prevalent among patients with severe COPD. The primary goal of pulmonary rehabilitation is to reverse muscular and cardiovascular dysfunction through an individually designed program. Most programs are multidisciplinary; in addition to exercise, they include education, behavior modification, and interventions to improve social and psychological functioning. A typical program consists of supervised sessions, each lasting 3 to 4 hours, provided 3 times weekly for 6 to 12 weeks. Major contraindications to the use of such programs are inability to walk, unstable cardiovascular disease, and cognitive impairment.

Randomized, controlled trials of pulmonary rehabilitation consist mostly of small, single-center studies, generally involving patients with severe disease according to spirometric criteria (FEV₁:FVC <0.70; FEV₁ < 30 to 49% of predicted value). A systematic review concluded that pulmonary rehabilitation significantly improved both functional exercise capacity (assessed by measuring the distance walked in 6 minutes) and respi-

ratory quality of life (evaluated on the basis of responses to the Chronic Respiratory Questionnaire). In the absence of a supervised continuation program, the improvement achieved during the active phase of rehabilitation erodes substantially over the following year.

**Surgical Options**

An option for selected patients with COPD is lung-volume reduction, which involves the resection of severely emphysematous tissue from both upper lobes, allowing the remaining lung tissue to expand and function more normally. In a randomized trial involving patients with severe COPD, this surgery was not associated with an overall reduction in mortality, as compared with the use of optimal medical therapy, although the surgery did result in improved lung function, exercise capacity, and respiratory quality of life. Mortality was reduced in the subgroup of patients who had predominant upper-lobe emphysema along with low exercise capacity at baseline; however, it should be noted that exercise capacity was not among the prespecified prognostic variables to be assessed.

Lung transplantation offers the only opportunity for severely disabled patients with COPD to resume normal daily activities, but the median survival rate after lung transplantation (about 5 years) remains far below that associated with the transplantation of other solid organs. It is not known whether the procedure reduces mortality, as compared with optimal medical therapy.

**Guidelines**

The Global Initiative for Chronic Obstructive Lung Disease, the American Thoracic Society–European Respiratory Society, and the American College of Physicians have published guidelines on the management of COPD (Table 4). The recommendations in this review are generally consistent with these guidelines.

**Areas of Uncertainty**

It remains unclear whether spirometry is routinely warranted to diagnose COPD in persons at risk who are asymptomatic. Whereas the National Lung Health Education Program has advocated widespread spirometric testing in medical offices (including testing in persons at risk who do not have respiratory symptoms) to identify cases of COPD, an evidence-based report sponsored by the Agency for Healthcare Research and Quality concluded that screening persons who are at risk but are asymptomatic would raise overall costs, falsely label many of those tested as having clinically significant disease, and only marginally improve clinical outcomes. In randomized trials, smoking-cessation rates were not increased among patients with early COPD who underwent spirometric testing and were informed of abnormal results, as compared with patients who did not undergo testing. However, in a recent trial comparing two approaches to informing patients of spirometric results — assigning a “lung age” versus simply reporting the FEV₁ — the former approach was associated with higher cessation rates at 1 year (difference, 7.2%), which suggests that spirometry may facilitate smoking cessation if the results are presented to patients in an appropriate manner.

The role of disease-management programs for patients with COPD remains uncertain. Randomized, controlled trials of case management for COPD have shown promise in reducing hospitalization rates, but the evidence is insufficient to make specific recommendations. Pulmonary rehabilitation improves health status and exercise capability for selected patients, but national surveys indicate that few patients complete such programs, and it is unclear how best to maintain the benefits achieved.

**Conclusions and Recommendations**

The patient described in the vignette has typical clinical manifestations of advanced COPD, with severe airflow obstruction confirmed by spirometry. Time should be allotted for education during the patient’s initial visit, including information about the signs and symptoms of a severe exacerbation and the need for prompt treatment. Smoking cessation is the most important element in the management of his disease and should be addressed at every visit, as long as the patient continues to smoke.

He should be treated with an inhaled long-acting β₂-agonist, an inhaled long-acting anticholinergic agent, or an inhaled corticosteroid.

† Data are from the Global Initiative for Chronic Obstructive Lung Disease.⁹
‡ Data are from Celli and MacNee.¹⁵
§ Data are from Qaseem et al.¹⁴
¶ GOLD identifies four stages of COPD, with 1 indicating mild COPD and 4 indicating very severe COPD.
Since he has severe, exacerbation-prone COPD, it would be reasonable to combine drugs from two of these three classes. A short-acting bronchodilator should be provided for rescue use. Even if symptoms do not abate, he should be urged to continue taking the medications, because they reduce the risk of a severe exacerbation. Like all patients, he should receive instruction in inhaler technique. (A video demonstrating inhaler technique is available at NEJM.org in an article by Heneles et al.)

If the patient’s arterial oxygen saturation is 88% or lower at rest in a stable clinical state, long-term oxygen therapy should be prescribed and used for at least 18 hours each day. In the absence of a contraindication, he should receive influenza vaccination each autumn, as well as pneumococcal vaccination (with revaccination as needed). Pulmonary rehabilitation should be considered if it is accessible to the patient and if he has no medical contraindications.
